REC'D 12 JAN 2004

WIPO PCT

I, the undersigned, being an officer duly authorised in accordance with Section 74(1) and (4) of the Deregulation & Contracting Out Act 1994, to sign and issue certificates on behalf of the Comptroller-General, hereby certify that annexed hereto is a true copy of the documents as originally filed in connection with the patent application identified therein.

In accordance with the Patents (Companies Re-registration) Rules 1982, if a company named in this certificate and any accompanying documents has re-registered under the Companies Act 1980 with the same name as that with which it was registered immediately before re-registration save for the substitution as, or inclusion as, the last part of the name of the words "public limited company" or their equivalents in Welsh, references to the name of the company in this certificate and any accompanying documents shall be treated as references to the name with which it is so re-registered.

In accordance with the rules, the words "public limited company" may be replaced by p.l.c., plc, P.L.C. or PLC.

Re-registration under the Companies Act does not constitute a new legal entity but merely subjects the company to certain additional company law rules.

Warning

After an application for a patent has been filed, the Comptroller of the Patent Office will consider whether publication or communication of the invention should be prohibited or restricted under Section 22 of the Patents Act 1977. You will be informed if it is necessary to prohibit or restrict your invention in this way. Furthermore, if you live in the United Kingdom, Section 23 of the Patents Act 1977 stops you from applying for a patent abroad without first getting written permission from the Patent Office unless an application has been filed at least 6 weeks beforehand in the United Kingdom for a patent for the same invention and either no direction prohibiting publication or communication has been given, or any such direction has been revoked.

Notes

- If you need help to fill in this form or you have any questions, please contact the Patent Office on 0645 500505.
- Write your answers in capital letters using black ink or you may type them.
- If there is not enough space for all the relevant details on any part of this form, please continue on a separate sheet of paper and write "see continuation sheet" in the relevant part(s). Any continuation sheet should be attached to this form.
- If you have answered 'Yes' Patents Form 7/77 will need to be filed.
- Once you have filled in the form you must remember to sign and date it.
- For details of the fee and ways to pay please contact the Patent Office.

SUB-MILLIMETRE WAVELENGTH CAMERA

The present invention relates to a sub-millimetre wavelength imaging device and particularly but not exclusively to an ambient 5 temperature terahertz camera using either single or multiple heterodyne detectors.

The terahertz electromagnetic spectrum extends over a range of frequencies where radio waves and optical waves merge and consequently the detection of terahertz radiation utilises a mixture of optical and radio 10 wave technology. It is known that at the low frequency end of the spectrum, e.g. 0.1 THz, radiation can be detected using an aerial in much the same way that a radio works although even for 0.1 THz the aerial must be only a millimetre in length. As a result of the dimensions of the individual components required to image at terahertz frequencies, the cost 15 of terahertz imaging systems has generally been prohibitive and requires cooling to very low temperatures.

However, terahertz frequencies have long been recognised as a potentially extremely useful frequencies for imaging purposes as many materials which are opaque in the visible region of the spectrum become 20 transparent to terahertz waves. In particular imagers at terahertz frequencies are suitable for imaging the Earth's surface as most weather conditions such as fog are transparent to terahertz waves. This also makes a terahertz imager a potentially useful imaging device when flying a plane or driving a land vehicle in bad weather, for example. The 25 transparency of many materials to terahertz frequencies has also been identified as a useful tool for security purposes. Most notably clothing becomes transparent at these frequencies enabling hidden weapons worn under clothing to be seen clearly and for spotting people hidden in canvas sided trucks and lorries. Furthermore, in view of the fact that human 30 bodies radiate at these frequencies, terahertz radiation has also been identified as a potentially powerful diagnostic tool for example in the early detection of skin cancers. Also, applications of terahertz imaging in the

chemical and food industries have been identified, for example in the detection of one or more constituents each having different transmissive/reflective properties at these frequencies.

The present invention therefore seeks to provide a terahertz imaging device capable of detecting low power passive terahertz radiation and of operating at ambient temperatures.

Accordingly the present invention provides a sub-millimetre imaging device comprising a pair of silicon substrates each patterned on at least one surface with co-operable patterning defining in combination an antenna, adapted to receive sub-millimetre electromagnetic radiation, a waveguide structure having a local oscillator signal input for connection to a local oscillator source and a mixing channel in communication with a via extending through one of the silicon substrates for connection to a signal output, the imaging device further including a mixer and associated filters mounted in the mixing channel defined by the co-operable patterning of the pair of substrates for extracting an intermediate frequency signal in dependence upon the sub-millimetre radiation receive by the antenna.

In a preferred embodiment the pair of silicon substrates have patterning defining in combination a plurality of antennae with respective mixing channels and local oscillator waveguide structures. Also, one of the pair of silicon substrates may be patterned on opposed surfaces and the imaging device may further comprise a third silicon substrate patterned on one of its surfaces such that the three substrates co-operably define by means of their patterning two rows of antennae and respective mixing channels and local oscillator waveguide structures.

In a further preferred embodiment the patterning of the substrates describe the mixing channel intersecting the local oscillator waveguide structure at an acute angle.

The present invention separately provides a method of fabricating a three dimensional structure in a substrate comprising applying to a surface of the substrate a plurality of differently patterned masks directly on top of one another and thereafter etching through a mask and then removing the

mask before repeating the process for each of the remaining masks.

Thus with the present invention a compact terahertz heterodyne detector is provided which is robust and capable of operating on low power. In a preferred embodiment the imaging device has a plurality of imaging 5 pixels for increased imaging resolution and is capable of generating multiple colour images.

An embodiment of the present invention will now be described by way of example only with reference to the accompanying drawings, in which:

10 Figure 1 is a schematic diagram of a two-colour terahertz camera in accordance with the present invention;

Figure 2 is an enlarged view of the detector of the terahertz camera of Figure 1;

15 Figure 3 is a photographic plan view of the waveguide structure employed in the terahertz camera of Figure 1;

Figure 4 is a photographic perspective view of the waveguide structure of Figure 2 illustrating the double-sided etching of the waveguide structure;

20 Figure 5 is a line drawing of the waveguide structure of Figure 2; and Figures 6a, 6b, 6c and 6d illustrates the fabrication steps for manufacture of the waveguide structure of Figures 2 and 3.

The terahertz camera 1 of Figure 1 comprises an X-Y stage 2 on which are mounted the scanning optics 3 and the terahertz detector 4 and a processor 5. The arrangement of the scanning optics 3 is conventional 25 and consists of two planar or parabolic mirrors 6, 7. Each mirror 6, 7 is movably mounted on respective orthogonal tracks 8, 9 and arranged to direct incident radiation from a specimen on a fixed specimen support (not illustrated) to the terahertz detector 4. Relative movement of the two mirrors 6, 7 on their tracks thus enables the specimen to be scanned in 30 orthogonal directions.

It will, of course, be appreciated that the mirrors 6, 7 should exhibit a high reflectivity to terahertz radiation in order to minimise losses especially

where passive radiation of a specimen is being imaged as the power of such radiation can be of the order of 10^{-12} W.

With the embodiment of the terahertz camera illustrated in Figure 1, movement of the two mirrors 6, 7 is controlled by separate linear motors 5 10, 11, which are preferably stepper motors to ensure precise positioning of the mirrors in the X-Y plane. Each of the motors 10, 11 includes a data port 12 that is connected to the processor 5 and feeds data on the instantaneous positions of the mirrors.

The terahertz detector 4 similarly includes an output data port 13 10 which is in communication with the controller 5. The controller 5, which is preferably a conventional desktop or portable computer, receives and synchronises the image data from the detector 4 and the positional data from the drivers of the motors 10, 11 and builds from the data an image of the scanned specimen. Conventional image capture software may be used 15 for this purpose. This image may be displayed on a screen and/or output to a printer as well as being stored as a conventional image file such as a .pdf file. As the specimen is being imaged on the basis of passive terahertz radiation then it is possible for the specimen to be imaged even through paper, as illustrated and many articles such as a gun (illustrated) is 20 preferably imaged in silhouette, for example against the passive radiation from a human body.

Turning now to Figure 2 the terahertz detector 4 is illustrated in detail the components of which are fabricated in or are mounted on a silicon machined structure an example of which is illustrated in Figures 3 25 and 4. The components of the detector 4 comprise a horn antenna 14 in the form of a Potter horn, which communicates with a tuned circuit 15 in the form of a waveguide which selectively receives a predetermined frequency of electromagnetic radiation ("signal input"). The tuned circuit 15 is in communication with a mixer 16 which is also in communication with a local 30 oscillator feed 17. The mixer 16 heterodyns the signal input and the local oscillator input so as to generate an intermediate frequency ("IF") output. The mixer 16 includes a first pass band filter 18 for isolating the local

oscillator input from the tuned circuit 15 and a second pass band filter 19 which acts as a back stop to allow through only the pre-selected IF output.

As can be seen in the Figures, the mixer 16 is arranged so as to be substantially orthogonal to the tuned circuit 15. However, the intersection 5 of the mixer 16 with the local oscillator feed 17 is not orthogonal and instead describes an acute angle of approximately 45°. This arrangement of the local oscillator feed at 45° to the mixer 16 reduces the back shot over a wider band width and so improves the bandwidth of the mixer transition in comparison to the more conventional 90° arrangement. Moreover, this 10 arrangement of the local oscillator input 17 and the mixer 15 provides an added benefit particular to imaging systems at these frequencies. The illustrated detector 4 consists of sixteen separate horn antenna providing a two-colour, eight pixel array. The size of the aperture of the detector 4 required to generate images at terahertz frequencies is such that the 15 spacing between the individual horn antennae is limited to approximately 2.5 mm in the illustrated example. This spacing is not sufficient to enable the more conventional arrangement of the mixer at 90° to the local oscillator feed and so the detector aperture presents a limit to the number of antenna. However, by arranging the local oscillator input feed 17 so that 20. it is substantially aligned with the horn antenna 14 and arranging the intersection of the mixer and the local oscillator feed 17 at 45° the number of antenna may be increased in the same area thereby improving the resolution of the detector.

It will, of course, be appreciated that whilst the illustrated 25 arrangement of the mixer 16 and local oscillator feed 17 is preferred especially where the detector consists of an array of antennae in order to increase resolution, the terahertz imaging system described herein is intended to also encompass more conventional arrangements of mixer and local oscillator feed.

As mentioned earlier, the terahertz detector 4 is fabricated from a 30 silicon machined structure consisting of three separate etched silicon

layers: a top layer 23, a middle layer 20 and a lower layer 24 which are illustrated in Figure 1. Figures 3 and 4 show the middle layer 20 which is etched on both its upper surface 21 and its lower surface 22. The upper layer 23 and the lower layer 24 are each etched on only one side and the 5 pattern of the etch in each case is a mirror image of the etch pattern of the respective upper surface 21 and lower surface 22 of the middle layer 20. Thus, whilst for each individual layer of silicon the etch pattern is open, when the three layers are brought together, the etch patterns of their 10 surfaces match to define waveguide structures extending along the interface of the surfaces. Co-operating location holes and pins 25 are also provided in the surfaces of each of the layers to ensure accurate positioning of the layers with respect to one another.

With reference to the middle layer 20, illustrated in Figures 3 and 4, 15 eight separate horn antennae are shown on the upper surface 21 of the middle layer 20. In Figure 4 the outline of a second row of eight horn antennae on the opposed lower surface 22 of the middle layer 20 can also been seen. Each horn antenna 14 is individually connected to its 20 respective tuned circuit 15 and mixer 16. Individual local oscillator feeds 17 connect with respective mixers but are themselves interconnected with one another upstream from the mixers to a single common local oscillator input 26. Thus, there are two separate local oscillator inputs 26, one for each 25 surface of the middle layer 20 (for each set of eight antennae) and preferably, these two outputs 26 emerge at the edge of the middle layer 20 at different locations for ease of connection to the local oscillator source (not illustrated).

The dimensions of the etch pattern defining the waveguide structure is important to the functioning of the detector 4 and these dimensions can be determined though conventional modelling techniques for example using a high frequency structure simulator (HFSS). The detector illustrated 30 in the figures is a two-colour detector with one of the set of eight antenna detecting a first terahertz frequency and the parallel second set of eight antenna detecting a second, different, terahertz frequency. This in turn

requires the dimensions of the etch pattern for each of the two sets of eight antenna to differ slightly depending upon the frequencies of the input signal and the local oscillator signal. Moreover, to maximise structural strength, it can be seen in Figure 4 that each row of horn antennae are offset from one another. The following measurements in relation to Figure 5 are therefore provided solely to illustrate typical dimensions.

Element Structure	Antenna Row 1 (mm)	Antenna Row 2 (mm)
a - Layer thickness	2.4	2.4
b - Layer width	25	25
c - Layer length	29	29
d - Cone angle of horn	23.5 °	27.7°
e - width of horn aperture	0.78	1.04
f - Width of signal input tuning circuit	0.1	3
g - distance of first branch of local oscillator feed from edge	12.74	11.62
h - distance of second branch of local oscillator feed from edge	7.86	6.62
i - distance of third branch of local oscillator feed from edge	5.36	4.42
j - Width of local oscillator feed adjacent mixer	0.39	0.43

Table 1

Downstream of the mixer 16, the IF output for each antenna passes to an outer surface of the silicon layered structure along a wire extending through a respective via 27. Thus a series of eight IF output vias extend

through the body of the top silicon layer 23 and a corresponding series of eight IF output vias extend through the body of the bottom silicon layer 24. From there the IF outputs pass through a conventional series of 2 stage amplifiers 28 to an integrated detector 29 and from there to the data input 5 port of the processor 5.

For detection of passive radiation at 250GHz, for example a local oscillator signal of 245 GHz may be used to extract an IF signal at 5 GHZ. It is to be understood that the frequencies quoted above are one illustration only and that conventional heterodyne theory can be employed 10 to identify other suitable local oscillator frequencies and IF frequencies.

With the detector described above, passive radiation at terahertz frequencies can be detected at room temperature and the use of a heterodyne receiver ensures a spectrally specific and sensitive detector. Although a two-colour eight pixel array is described, it is immediately 15 apparent that a single antenna terahertz camera comprising only two layers of patterned silicon may be implemented in the manner described above. Moreover, further layers of patterned silicon may be added with in each case the common local oscillator input 26 being located at different positions along the periphery of the silicon layers. However, where more 20 than two rows of antenna are provided, the IF output vias must pass through intermediate silicon layers, avoiding the waveguide structure of that layer, and so the patterning of the antennae for different antennae rows should be offset from each other.

Furthermore, it is envisaged that rather than using a slab of intrinsic 25 silicon for the fabrication of the individual waveguide structures, the antennae may be fabricated in photonic bandgap material. This would prevent signal leakage between adjacent antennae and could provide an alternative structure for the mixer and for the conduction of both the signal input and the IF output.

30 The waveguide structure described above requires deep etching of the individual silicon layers and a novel method of fabricating these structures is described below. With reference to Figure 6a a silicon

substrate 30 is illustrated on the upper surface of which is provided a series of three masks 31, 32 and 33 each laid on top of the next and in direct contact with the adjacent mask. In order from the top the first uppermost mask 31 is a positive resist or a metal mask. Directly beneath the first 5 mask is a second negative resist mask 32 such as SU8 or other suitable amide mask material. Beneath the second mask is a third mask 33 preferably of silicon dioxide or aluminium nitride. The first mask 31 defines the deepest structures in the substrate and protects other areas from early etching. The second mask exposes, in addition to the deepest etch 10 regions, intermediate depth etch regions whilst protecting those regions of the substrate that require the shallowest etch. The third and final mask exposes all areas previously etched as well as those areas requiring the shallowest etch.

With regard to the waveguide structure described above, the 15 deepest etches are patterned for the horn antenna and the tuned circuit, the intermediate etch depth is required for the majority of the local oscillator waveguide structure and then the shallowest etching is required for the mixer channel. Once all of the individual masks have been applied, the first etch is performed using the positive resist mask 31. The etch is continued 20 to an etch depth equivalent to the difference between the desired final depth of the deepest structures and the final depth of the intermediate structures. The positive resist mask 31 is then removed (Figure 6b) using a normal stripper such as an amine type stripper which does not affect the underlying negative resist mask 32. The next etch stage is then performed 25 through the SU8 mask 32 to a depth equivalent to the difference between the desired final depth of the intermediate structures and the shallowest structures. As the etched pattern from the first etch stage remain exposed this pattern is again etched and the pattern driven deeper into the substrate. Once the second etch is completed the second mask 32 is 30 removed (Figure 6c) which does not affect the underlying third mask 33 and then the third and final etch stage can be performed during which the shallowest features of the pattern are etched and the existing pattern again

etched more deeply into the substrate 30 to its final depth. The third mask 33 is then removed (Figure 6d). This procedure differs from then conventional procedure as it involves the use of a plurality of different masks each directly overlying an adjacent mask and an etching procedure 5 in which new masks are not applied to the surface of the wafer in between etching steps.

Although reference has been made herein to the use of a convention X-Y stage for scanning a specimen by means of a static terahertz camera and mobile scanning optics it will, of course, be apparent that alternatives 10 to this arrangement are envisaged. For example, the specimen may be mounted on an X-Y stage and moved so that different areas of the specimen are scanned in turn.

Alternatively, scanning may be performed wholly electronically through adjustment of the phase of the local oscillator input. In this regard 15 a phase shifter (not illustrated) has been developed for introduction into the individual local oscillator feeds 17 which is the subject of a co-pending patent application. In brief, the phase shifter consists of a waveguide which has a slab of high resistivity intrinsic silicon mounted on the inside of one wall of the waveguide. A series of slits cut into that wall of the waveguide 20 expose the slab of silicon to incident light which causes the silicon to exhibit metallic properties. The power of the incident light determines the depth to which the changes in the silicon penetrate and thus establishes a reflective interface within the slab of silicon, the position of which can be varied with respect to the power of the incident light.

25 The imaging device described herein is suitable for the detection of passive millimetre and sub-millimetre electromagnetic radiation and in this respect is particularly convenient in view of its compact size, potential for portability and its ability to perform at room temperature. Thus, immediate applications for the imaging device are envisaged in both airborne and land 30 vehicles, in security systems, in the chemical and food industries and in medical diagnostics. However, the scope of applications is not limited to those identified above and because of the low power requirements of the

imaging system, it is particularly suited for example to imaging from space.

It will, of course, be apparent that alternative components and alternative manufacturing techniques may be employed without departing from the scope of the present invention as defined in the appended claims.

CLAIMS

1. A sub-millimetre imaging device comprising a pair of silicon substrates each patterned on at least one surface with co-operable patterning defining in combination an antenna, adapted to receive sub-millimetre electromagnetic radiation, a waveguide structure having a local oscillator signal input for connection to a local oscillator source and a mixing channel in communication with a via extending through one of the silicon substrates for connection to a signal output, the imaging device further including a mixer and associated filters mounted in the mixing channel defined by the co-operable patterning of the pair of substrates for extracting an intermediate frequency signal in dependence upon the sub-millimetre radiation receive by the antenna.
- 15 2. The sub-millimetre imaging device as claimed in claim 1, wherein the pair of silicon substrates have patterning defining in combination a plurality of antennae with respective mixing channels and local oscillator waveguide structures.
- 20 3. The sub-millimetre imaging device as claimed in either of claims 1 or 2, wherein one of the pair of silicon substrates is patterned on opposed surfaces and the imaging device further comprising a third silicon substrate being patterned on one of its surfaces such that the three substrates co-operably define by means of their patterning two rows of antennae and respective mixing channels and local oscillator waveguide structures.
- 25 4. The sub-millimetre imaging device as claimed in any one of the preceding claims, wherein the patterning of the substrates describe the mixing channel intersecting the local oscillator waveguide structure at an acute angle.
